19 1 Introduction

In the field of Biology, mathematical models can be used to explain or describe natural phenomena and observations. This method of modelling can be applied especially in the 21 field of Ecology and Evolution. Models are a simplistic method to describe the general behaviour of long-term macro-biological events noticed in nature (Johnson & Omland 2004). A field in Ecology is Population Ecology, and simplified models can validate the dynamics of population growth and how different factors and conditions affect the population numbers over time. The models chosen are generalised models describing bacterial growth. Therefore, they disregard the capacity for evolution, classifying the organisms as homogenous (Levins 1966). Finding the best fit will be achieved by fitting suitable models and evaluating the best fit to the data using either maximum likelihood or least squares (Johnson & Omland 2004). Model fitting has become an alternative approach to the traditional null hypothesis tests when carrying out scientific experimentation. If carried out properly, parameters and overall function of the model are used to make biological inferences on the patterns recorded (Johnson & Omland 2004). The challenge, however, is finding the appropriate model and taking into considerations the assumptions and trade-offs of the different models. 35 Models aim explain the important aspects of the data, thus have many assumptions. When choosing a model, it is important to account for the trade-offs between generality, realism 37 and precision, focusing on model that sustain generality and realism, as they are able to quantitatively explain long-term trends that the data reveals (Levins 1966). In other words, the purpose of the model, and what is being investigated is an important factor. In addition to this, ensuring that the parameters have biological significance rather than just statistical significance (Johnson & Omland 2004). For this project, identifying the correct model is achieved through the process of testing multiple existing mathematical and biology models on the data and finding the model that best fits the data using the analytical method of Maximum Likelihood. The outcome should be plausible models that for most observed data, consistently describes the patterns in these observations mechanistically or empirically. 47 The focus of this project is to test multiple non-linear regression models on microbial population data. Identifying the best model(s) that best fit and or describe the pattern of the data. Microbes grow through a process known as binary fission, doubling the population continually (Webb 1986). This exponential growth coupled with limiting factors gives microbial population growth a sigmoidal shape which can be divided into four phases (Peleg & Corradini 2011). The trend begins with birth, a starting population (N0) and growth where limiting factors is not yet inhibiting, thus having an exponential growth curve, with a growth rate notation of r (Zwietering, Jongenburger, Rombouts & Van't Riet 1990). Limiting factors such as space, nutrients and particularly carrying capacity can inhibit growth, resulting in the rate of growth to decrease and eventually reaches saturation, becoming asymptotic. The asymptotic value being the carrying capacity, with the notation $N_m ax$ (Zwietering et al. 1990).

Four mechanistic models will be tested on the data set. These are the Logistic Growth Model (Bacaër 2011), Baranyi Model (Baranyi,1993), Gompertz Model (Zwietering et al.

1990) and Buchanan Model (Buchanan, Whiting & Damert 1997), 1997), given below.

Logistic Model

$$N_t = \frac{N_0 \cdot N_{max} \cdot e^{r_{max} \cdot t}}{N_{max} + N_0(e^{r_{max} \cdot t} - 1)}$$

$$\tag{1.1}$$

Baryani Model

$$N_t = N_{max} + \log_{10}\left(\frac{-1 + \exp(r_{max} \cdot t_{lag}) + \exp(r_{max} \cdot t)}{\exp(r_{max} \cdot t) - 1 + \exp(r_{max} \cdot t_{lag}) \cdot 10^{(N_{max} - N_0)}}\right)$$
(1.2)

Gompertz Model

$$N_t = N_0 + (N_{max} - N_0) \cdot \frac{\exp(-\exp(r_{max} \cdot \exp(1) \cdot (t_{lag} - t)))}{(N_{max} - N_0) \cdot \ln(10) + 1})$$
(1.3)

Buchanan Model

$$N_{t} = \begin{cases} N_{0}, & \text{if } t \leq t_{lag} \\ N_{max} + r_{max} \cdot (t - t_{lag}), & \text{if } t_{lag} < t < t_{max} \end{cases}$$

$$N_{max}, & \text{if } t \geq t_{max}$$

$$(1.4)$$

Model fits be will be assessed using the Akaike Information Criterion (AIC), which is a relative comparison where the best fit is the model with the minimum value (Vrieze 2012, ?). The AIC is a criterion used to assess the model fits. It is a relative measure of the Kullback-Leibler divergence estimate. Meaning that whereas the K-L divergence measures

the deviation of a model from the "true model", the AIC is an estimate value only between the models considered (Vrieze 2012). It consists of two variables, the likelihood function (a loss function) which results in a Maximum Likelihood Estimate of the parameters, and the number of parameters in the model (Vrieze 2012). The formual is given below, where α is known as the penalty coefficient (with a value of 2), κ is the number of parameters and \mathcal{L} is the Maximum Likelihood Estimate of the parameters.

Akaike Information Criterion

$$AIC = -2 \cdot \ln\left(\mathcal{L}\right) + \alpha \cdot \kappa \tag{2}$$

Lastly, an additional investigation on the correlation between growth rate and temperature is also carried out. In addition to this, compare two models, a linear model and a relationship formula given by *Ratkowsky et al.* Given the range of temperature from 0 degrees Celsius to 37 degrees Celsius, the expectation is to see a positive linear relationship between increasing temperature and growth rate. Species and medium are factors considered and a linear regression anlaysis is done, as well as plotting the formula from *Ratkowsky et al.* given below.

$$\sqrt{r} = b(T - T_0) \tag{3}$$

I will call this formula the Conceptual Temperature model. The parameter T_0 is the conceptual temperature, a hypothetical temperature which has no metabolic significance, in which other factors such as medium are non-limiting (Ratkowsky, Olley, McMeekin & Ball 1982) Conceptual temperatures for different species are provided from Ratkowsky et al. paper and used to identify the relationship between growth rate and temperature and see if the model performs better than a linear regression.

86 2 Methods

In this project, published data was provided on multiple experiments on microbial population and growth.Growth conditions including medium and temperature were manipulated and populations were recorded through different measurements techniques such CFU, or OD595. The Population numbers and time were recorded discretely at different time intervals. The data were stored in a .csv file, LogisticGrowthData.csv. All four mechanistic 92 models were fitted on the data.

2.1 Computing Tools

94 Python

Python software was used to wrangle the data. The data provided was in one large .csv file and needed to be manipulated before being filtered. Combination of functions and commands were used to wrangle the data and remove unwanted data points, as well as

converting to log space. Pandas and Numpy were the two packages used for the purpose

of data import and carrying out mathematical manipulations of the data set.

100 R

R software was used to filter the data set and carry out data analysis. Software package dplyr was used to filter the data set and create unique ID's, which were saved as .rda files. The mechanistic equations to be fitted on the data and functions to find optimal 103 starting value for the parameters were done in R. Using minpack.lm package, non-linear 104 regression analysis was carried out using the nlsLM() function as well as plotting the 105 different unique analysis. The package BisRNA was used to perform fisher's method to 106 get a p-value statistic from multiple independent tests for the linear regression of growth rate and temperature. The stringr package was used for setting wrappers and filtering the unique species by their string. Lastly, gridExtra package was used to save tables from R 109 in pdf format. 110

111 Bash

Bash script was used to run the python, R scripts and the latex file, to convert the latex into a pdf.

114 2.2 Data Exploration and Filtering

The data was first wrangled before being filtered. All abundance recordings of OD595 were first multiplied by 100. Next the data was treated in linear scale, therefore negative time and population values were either removed or shifted. In addition, negative time values were set to zero as it is not realistic to have a negative time recordings. The data was then transformed to a log scale, by taking the common logarithm of the population abundance. This is to fit the criteria of three of the models and make the data less skewed.

Although the Logistic model is not in log scale, the output value is of the function is, to maintain the linearity of the function, and interpret the paramters biologically.

Data was then filtered based on the headings: species, medium, temperature, citation and replicate. It is important to note that method of collecting population count was not a factor in the model fitting and assessing of best model(s). The unique data sets were saved in .rda files which included the unique ID's and a data frame of the time intervals, labelled Time and the common logarithm of the population count at each discrete time interval, labelled Abundance.

The four mechanistic models were then fitted to all the different sub-data sets. Of the four, the Logistic formula is derived from bacterial growth properties, where r_{max} is the maximum growth rate during the exponential phase and N_{max} represents the carrying capacity, while the other three models are based on mathematical derivations. However, since all the models utilise the same parameters, their values can be interpreted to have the same biological interpretations (Levins 1996). Using R Programming Language, each of the models will be tested on the data and the Akaike Information Criterion (AIC) will be the statistic to analyse the model of best fit.

137 2.3 Fitting the models

The R software will be used to test the models and their fits. Using the package minpack.lm, the nlsLM() function is used to fit the non-linear mechanistic models. Since it is non-linear regression fitting, parameter starting values must be estimated within range of the global maximum or minimum respectively as unlike linear regression, the function can find an optimal value, but only be a local rather than a global minimum or maximum. To fit the Baranyi, Gompertz and Buchanan models, it requires inputting four starting parameter values $(N_0, t_lag, r_{max}, N_{max})$ for the parameters of the equation, while the Logistic model only requires three of the parameters, not including t_lag .

46 2.4 Finding Parameters

 N_0 is the starting population value at the first-time recording, thus the first data point. The carrying capacity (N_{max}) is the largest value found in the data set, which is the maximum value of the data set. The growth rate, r_{max} , is the largest gradient value of the derivative found at the point $\frac{N_{max}}{2}$, otherwise known as the inflection point. To find the estimate of this parameter, a function utilising a while loop was used. It describes the

rate of change of the population over time, given the equation below:

$$\frac{dx}{dt} = \frac{x_{t+1} - x_t}{(t+1) - t} \tag{4}$$

where dx represents the change in population count from time t to t+1. Starting from the first data point and progressing to the final two data points, each iteration calculated the slope between adjacent data points, saving all results in a vector and the largest value was taken to be the r_max .

The models include a time lag, which is a delay in time of bacteria growth. The estimation is found through the intersection between the lag phase, which can be represented by the starting population value, and exponential growth phase, represented by the slope of the growth rate (Peleg & Corradini 2011). This was calculated by the intersection of $y=N_0$ and the line with gradient r_{max} . Using the y-intercept (y_{int}) value from the r_{max} line that produced the greatest slope, rearranging of the linear equation leads to the formula:

$$t_l a g = \frac{N_0 - y_{int}}{r}$$

Figure 1 below shows an example of this derivation.

Species and medium were the factors accounted for when identifying the correlation between temperature and growth rate. For each of the unique ID's, the growth rates, temperatures, Species and growth medium were recorded in a large matrix. The matrix was subset to the different unique ID's and linear regression analysis was done to analyse the correlation.

2.5 Fitting Analysis

All models were fitted on all of the data and the best fits were analysed using the Akaike Information Criterion (AIC), which measures the amount of lost information when fitting the models (Posada & Buckley 2004). We are using AIC to assess the model fit as it is able to analyse nested and non-nested model fits as well as being less penalising for additional parameters unlike BIC (Posada & Buckley 2004). In this case, the four mechanistic models which all have similar parameters with t_{lag} being the additional parameter.

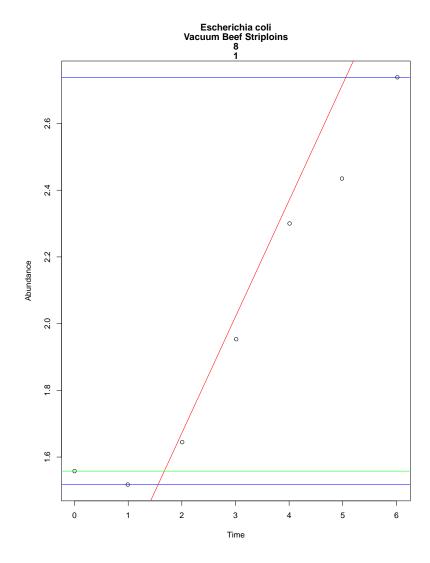

Figure 1: The first replicate of species Escherichia coli grown in medium of Vacuum Beef Striploin at a temperature of 8°C. The blue lines represent N_0 (lower blue line) and N_{max} (upper blue line). The red line represents the slope representing r_{max} . Finally the green line is the estimate of the t_{lag} , where x-value of the intersection of the red and green is the parameter estimate.

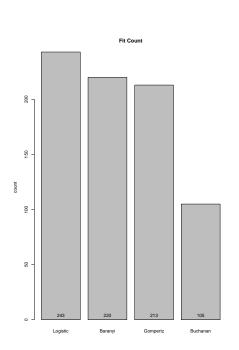

64 2.6 Additional investigation

Aside from identifying the best fit model, another aspect being investigated is the correlation between growth rate and temperature. The models used despite their derivations contain the same parameters, having a unified theory for the bacterial growth behaviour (Levins 1966). Investigating how the growth rate changes as temperature increases through linear regression for each of the unique species and mediums will give insight if the trends are similar. A linear regression was compared to the formula found in the paper of *Ratkowsky et al.* The correlation coefficients from the linear regression and p-values of the slope coefficients were recorded and saved in a table.

$_{\scriptscriptstyle 3}$ 3 Results

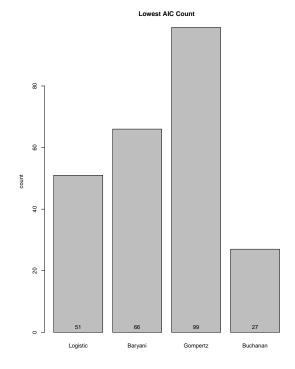

Filtering and wrangling the data resulted in 305 different unique sub-data sets being produced, saving the data frames of time and common logarithm of the population, and the respective unique species ID in .rda files. The plots to show the trend in population over time has time along the x-axis and Abundance along the y-axis. Plots revealed an inconsistent distribution of the data set, some sigmoidal, log distributed or completely random. All starting parameter values were generated for 298 of the 305 data sets and any negative growth rate slopes r_{max} was set to NA.

Optimal parameter values were obtained for most of the unique data sets. The Buchanan model had 105 fits, Baranyi model had 218 fits, Gompertz model had 211 fits and finally the Logistic model had the most with 241 fits. The models fit approximately 80

(a) Figure 2.1: Barplot of the number of successful fits for each model

183

(b) Figure 2.2: Barplot showing count of lowest AIC scores for each of the models tested on the data

In the additional investigation from the paper, conceptual temperature recordings existed for five of the species from the published data. These five species and their data were subsetted, and linear regression analysis was carried out. The plots include two lines, the

linear regression line, and the formula

$$\sqrt{r} = b(T - T_0)$$

(Ratkowsky et al. 1982). Temperature along the x-axis was plotted against \sqrt{r} on the y-axis as recommended by Ratkowsky et al. Visualisation of the results shows that the growth rate is positively correlated with temperature, with an average value of 0.958, with an overall p-value of $1.01 \cdot 10^-9$ for the slopes. This suggests very strong positive correlation between growth rate and temperature. Temperature is treated to be a continuous variable and as the temperature increases, growth rate will increase as well. Ratkowsky et al. showed plotting the square root growth rate against the temperature values, leads to a distribution that is linear.

92 4 Discussion

191

4.1 Wrangled data and starting parameters

When visualising the data, the common log of the abundance produced either a slight sigmoidal func-195 tions or log distribution, which is expected. Distri-196 bution of the data sets were not consistent as some plots revealed no pattern, having a random distribution of points along the axis, unable to derive starting parameter values and overall fit the models. Fur-200 thermore, some of the data sets revealed a decline 201 once the asymptotic value has been reached. This is 202 the death phase which is ignored in the model fitting process (Zwietering et al., 1990).

5 Getting all required starting parameters is necessary

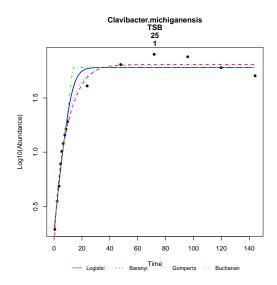

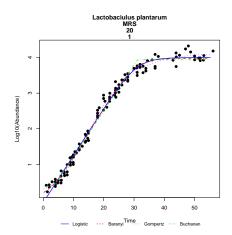

Figure 3: Clavibacter michiganensis model fit showing the death phase

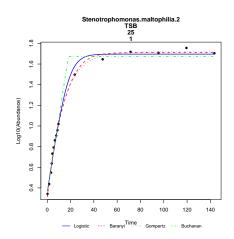

of for the model fittings to be produced. Despite not

all the data sets followed a sigmoidal or log distribution, positive r_{max} and t_{laq} values were 207 still derived from all the data sets. Although the Logistic model only requires three of the starting parameters, the growth rate parameter is the determining factor of all the models 209 fitting. Starting population (N_0) and carrying capacity (N_{max}) are easily derived from the 210 data sets however, growth rate and time lag are mathematical derivations thus have the 211 possibility of having NA values depending on the distribution of data points. The growth 212 rate coefficient represents the max slope between points, which is the derivative along the inflection point. While the t_{laq} requires the y-intercept of r_max slope as well as the actual 214 slope value to derive it. 215

$_{16}$ 4.2 Model fitting

(a) Figure 3.1: Lactobaciulus plantarum model fit

(b) Figure 3.2: Stenotrophomonas maltophilia model fit

All four models were nested upon each other, utilising similar parameters. The Logistic model is derived from external limiting factors including resource and density. These ex-218 ternal factors play limit the exponential growth of the population, hence producing the 219 sigmoidal shape where it reaches an asymptotic value known as the carrying capacity 220 (Webb 1986). The Baranyi model is a differential model which accounts biological factors 221 of individual microbial growth. It takes into account environmental variation and the physiological limiting factors, specifically the limits in the rate of biochemical reactions within the microbe (Buchanan et al. 1997, ?). The Buchanan model is a simplified version of the Gompertz model and Baranyi model, which accounts for biological variability, 225 considering individual physiological factors and population factors such as adaptation at 226 each of the growth phases to produce a three-phase linear model (Buchanan et al. 1997) et al., 1997).

Overall, the results show that the Gompertz model was the most robust model, having the greatest number of goodness of fit. In other words, for the provided data set, it is 230 the best model to describe the population dynamics of microbial growth over time. This is not surprising as it is a primary level model, which only describes change population 232 over time (Grijspeerdt & Vanrolleghem 1999). The Gompertz model is mathematical 233 derivations to form the sigmoidal relationship (Buchanan et al. 1997) et al., 1997). Despite 234 its parameters, it is an empirical derivation not accounting for any biological processes. 235 The robustness of the model is from the parameters. The parameters account for shape or curvature of the fit, and location along the axis, allowing the model to shift the fit along the x-axis or y-axis and maintain its overall shape (Tjørve & Tjørve 2017). Furthermore, 238 similar to the method of deriving the growth rate from the data sets, the growth rate in 230 the Gompertz model is derived along the inflection point.

241 **4.3** AIC

Best fitting model was determined through the AIC values produced. From the results, the Gompertz model was the most robust, having the most number of fits. This is due to the derivation and robustness of the parameters, as well as the flexibility of the model (Tjørve & Tjørve 2017). Depending on the data set, the AIC values produced negative or 245 positive ranges of values, and the best model fit was the model that produced the minimum 246 value relative to the other fits. The AIC values here shows that Gompertz model most likely explains the data sets however, cannot explain how "true" realism, since we are only comparing relatively between the four models. AIC considers the trade-off between model complexity and fit (Vrieze 2012). AIC does favour more complex models as from the 250 formula, the $-2 \cdot \mathcal{L}$ is decreased (Posada and Buckley, 2004). This is why the Gompertz 251 model performed well as it contains four parameters. The extra parameter in addition with the flexibility of the model itself makes it a robust fit.

254 4.4 Temperature and Growth Rate Correlation

	Species	Conceptual Temperature
1	Aerobic Mesophilic.	-0.25
2	Escherichia coli	1.85
3	Pseudomonas sp.	-7.15
4	Pseudomonas spp.	-8.05

Table 2: Provided conceptual temperatures of species in data set

Using the species with recordings of conceptual temperature, the plots show that there is a strong positive correlation between growth rate and temperature. A linear regression analysis was done and also fitting the the formula given from 258 Ratkowsky et al. Unlike the original paper, the distribution of 259 points were not as linear but this is likely due to data collec-260 tion methods from the data provided as well as the temper-261 ature tolerances of the different species. Using the linear regression analysis, x-intercept values were calculated to see 263 if they coincide with conceptual temperatures (Ratkowsky 264 et al. 1982). The x-intercepts vary from the conceptual tem-265 peratures provided from the paper. From the plot, aside from 266 the Aerobic Mesophilic in Cooked Chicken Breast, the Con-267 ceptual Temperature model did not align with the data well.

Furthermore looking at the regression analysis, if we use a

269

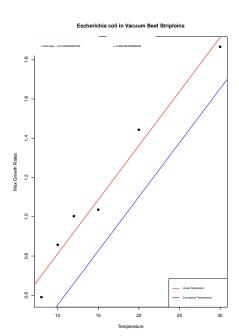

Figure 5: Escherichia Coli recorded growth rates plotted against temperature

significance value of 0.05, using fisher's method for independent test statistics, which
takes the logarithm of the p-values (Fisher 1992, p.103). The resulting p-value is much
less than the significant level. This means that the slopes are statistically significant, not
random and support the positive correlation between temperature and growth rate. Only
five species were investigated but further analysis can be done as conceptual temperature
values are collected for the other species in the provided data. Overall, the results show
that temperature and growth rate are positively correlated.

₇ 5 Conclusion

In conclusion, the Gompertz model performed well due to its derivations. As mentioned in the Discussion, the parameters and its values are empirically derived. Similar to the Logistic model, its parameters do not consider the physiology or limiting factors of the organism, just the rate at which it divides. Furthermore, compared to the Logistic model, it takes in an extra parameters that makes it more robust and flexible.

When fitting models, there is a tradeoff between realism and complexity. Although complex plex models, which contain more parameters, will fit the given data set better. This is however, all dependent on the context and purpose of study. In this research, the focus was on models that can explain the patterns and trends in the data, and would fit well relative to the others. Only two models, Baranyi model and Buchanan model actually considered organismal physiology and further model fitting can be done using other biologically mechanistic models that take into account internal and external factors.

For the additional investigation, although the distribution of the data did not match that from the study carried out by *Ratkowsky et al.*, and only used five species, the overall result still supports the claim that growth rate is positively correlated to increases in temperature. However, the derived conceptual temperature from the linear regression did not match that provided from the paper. Replication and additional investigation can be carried out to see if increased dataset leads to this condition, and if the positive correlation hold true for the other microbes.
